

Hedgehog Signaling Pathway ^[1]

By: Haskett, Dorothy R. Keywords: Hedgehog ^[2] hh ^[3] signaling pathway ^[4]

The hedgehog signaling pathway is a mechanism that directs the development of embryonic cells in animals, from invertebrates to vertebrates. The hedgehog signaling pathway is a system of [genes](#) ^[5] and gene products, mostly proteins, that convert one kind of signal into another, called transduction. In 1980, [Christiane Nüsslein-Volhard](#) ^[6] and Eric F. Wieschaus, at the [European Molecular Biology Laboratory](#) ^[7] in Heidelberg, Germany, identified several fruit fly (*Drosophila melanogaster* ^[8]) [genes](#) ^[5]. They found that when those [genes](#) ^[5] were changed or mutated, the mutated [genes](#) ^[5] disrupted the normal development of fruit fly larvae. The researchers called one of the [genes](#) ^[5] *hedgehog* (abbreviated *hh*). Nüsslein-Volhard, Wieschaus, and [Edward B. Lewis](#) ^[9], at the [California Institute of Technology](#) ^[10] in Pasadena, California, shared the 1995 Nobel Prize for Physiology or Medicine for their research on how [genes](#) ^[5] control early embryonic development in fruit flies. The hedgehog signaling pathway is conserved across many animal taxa, or phyla, from [Drosophila](#) ^[11] to [humans](#) ^[12]. The hedgehog signaling pathway controls several key components of embryonic development, stem-cell maintenance, and it influences the development of some cancers.

In the 1970s, Nüsslein-Volhard and Wieschaus studied mutations in [genes](#) ^[5] that altered the head to tail (anterior-posterior) body plan of [Drosophila](#) ^[11] larvae. The larval body plan of normal [Drosophila](#) ^[11] is composed of segments. Nüsslein-Volhard and Wieschaus in their 1980 article identified several genetic mutations that disrupted the [Drosophila](#) ^[11] larval body plan, including segment number, the pattern of the segments, and their orientations. The anterior portion of the bottom, or ventral, side of each segment is marked with a row of pointed cuticle projections, called denticles. The posterior portion is devoid of denticles, and is described as naked. Nüsslein-Volhard and Wieschaus found that several gene mutations caused the denticles on a larva to duplicate in number, resulting in loss of all or some of the naked portions of the larva's segments.

In one gene mutation, the denticles sticking out of the segment in all directions formed a pattern that resembled that of a hedgehog's spines, prompting Nüsslein-Volhard and Wieschaus to name the mutated gene *hedgehog*. They designated the *hh* gene as a segment [polarity](#) ^[13] gene because the duplicated denticles were oriented in the reverse direction from the normal denticles, a phenomena described by researchers as having reverse [polarity](#) ^[13] in each segment.

Into the early 1990s, most of the research about the *hh* gene concentrated on the *hh* gene in [Drosophila](#) ^[11]. Researchers analyzed the fruit fly *hh* gene and manipulated cells within developing [Drosophila](#) ^[11] embryos, or fragments of the embryos grown in lab cell cultures. Researchers determined that the *hh* gene encodes a novel signaling family of hh proteins that mediates interactions between cells and has long-range effects in developing [Drosophila](#) ^[11] embryos. In 1985, Alfonso Martinez-Arias and Philip W. Ingham in the UK reported that for [Drosophila](#) ^[11] larvae to develop normally, segment [polarity](#) ^[13] [genes](#) ^[5] had to be expressed precisely and with integration to [genes](#) ^[5] that control the [differentiation](#) ^[14] for each segment,

called homeotic [genes](#) [5].

In 1992, three groups published descriptions of the complete DNA sequence of *hh* gene in [Drosophila](#) [11]. The first included Jym Mohler and Kodela Vani at Barnard College in New York, New York. The second was Phillip A. Beachy's group at [Johns Hopkins University School of Medicine](#) [15] in Baltimore, Maryland. The third was Thomas B. Kornberg's group at the University of California at San Francisco, in San Francisco, California. The analysis of the DNA sequence data of the [Drosophila](#) [11] *hh* gene led to the discovery of similar [genes](#) [5], or homologs, of the [Drosophila](#) [11] *hh* gene in vertebrates. The DNA analysis also revealed a high degree of conservation of the parts of the hedgehog signaling pathway among and between species. In December 1993, other research groups published descriptions of the complete DNA sequences of several homologs to the [Drosophila](#) [11] *hh* gene in vertebrates.

Unlike flies, which have only one *hh* gene, researchers found that there are several *hh genes* [5] in vertebrates, including upwards of five *hh genes* [5] in zebrafish, and three *hh genes* [5] in mammals. Ingham's group at the Molecular Embryology Laboratory in Oxford, UK, identified the *hh* gene family in zebrafish (*Danio rerio* [16]). Clifford Tabin's group at [Harvard Medical School](#) [17] in Boston, Massachusetts, isolated the vertebrate gene *Sonic hedgehog* (*Shh*), which is related to the [Drosophila](#) [11] *hh* gene. The scientists isolated the gene from the area that genetically instructs the developing limb, or limb bud, called the zone of polarizing activity (ZPA) in chicks (*Gallus gallus* [18]). Andrew P. McMahon's group at [Harvard University](#) [19] in Cambridge, Massachusetts, identified three members of the *hh* gene family in mice (*Mus musculus* [20]). They labeled those three [genes](#) [5] as *Shh*, *Desert hedgehog* (*Dhh*), and *Indian hedgehog* (*Ihh*). By 2015, researchers had concluded that the protein sequence of the *Dhh* protein is the most closely related of the three gene products to the [Drosophila](#) [11] *hh* protein. *Ihh* and *Shh* DNA sequences indicate that those [genes](#) [5] are more closely related to each other than to the *Dhh* gene, and scientists said that those two [genes](#) [5] resulted from a more recent evolutionary duplication.

[Drosophila](#) [11] *hh* gene and vertebrate homologs function to provide cells with [positional information](#) [21] in developing organisms. [Drosophila](#) [11] embryos lacking *hh genes* [5] die, revealing changes in their cuticle pattern, which suggests that [Drosophila](#) [11] require the gene for survival. In [Drosophila](#) [11], in addition to its role in patterning embryonic segments, the *hh* gene expression is in parts of the insect larvae that become the adult legs and wings, called the imaginal discs. The imaginal discs are similar in developmental function to the limb buds in vertebrates.

The hedgehog signaling pathway participates in the development of many tissue and organs. M. Michael Cohen, Jr., at [Dalhousie University](#) [22] in Halifax, Nova Scotia, titled his 2003 article "The Hedgehog Signaling Network," due to the complexity of the interactions between the many [genes](#) [5] and secreted *hh* proteins. The hedgehog signaling network incorporates many [genes](#) [5] and proteins to function correctly. The hedgehog signaling network influences the transcription of many different target [genes](#) [5] that vary between tissues, cell types, and phylas.

By the second decade of the twenty-first century, the description of the hedgehog signaling pathway consisted of at least two parts, which were the cells that produce *hh* protein, and the cells that respond to the *hh* proteins. From *hh genes* [5] in the DNA of its [nucleus](#) [23], a cell that produces the protein first transcribes the *hh* protein as a string of amino acids, called a precursor protein, and processes the protein in the cell's cytoplasm, a process that yields an

active protein with two lipid molecules. The two lipid molecules are a cholesterol on the C-terminal end of the active protein, and the lipid palmitate on the N-terminal end of the active protein. The two lipid molecules are necessary for the hh protein to be transported and attached to the cell surface membrane, and to establish a gradient of the protein in the extra cellular space. The processed hh protein is transported to the cell surface where it attaches with the lipid molecules to the outside of the cell membrane. Another protein embedded in the membrane, called a trans-membrane protein, named Dispatched, releases the active hh protein, called the hh ligand, into the space between cells, called an extra cellular space, where multiple hh ligands form a concentration gradient.

Other cells respond to the hh proteins. Each one of those cells has a protein, called Patched (Ptch), that spans through the cell's membrane and functions as a receptor for the hh ligand by physically attaching to it. Without the hh ligand attached to it, Ptch normally inhibits another trans-membrane protein called Smoothed (Smo), which itself prevents specific [genes](#) [5] from transcribing RNA. When the hh ligand binds to the Ptch protein, it activates the Smo protein. The Smo proteins interact with other molecules, which interact with others, in a process described as the hh signal cascading or transducing through the cell's cytoplasm and into the [nucleus](#) [23]. Finally, molecules, connected in a chain or pathway of molecular interactions that was spurred by the hh ligand, attach to parts of the DNA in the [nucleus](#) [23], and they initiate specific [genes](#) [5] to produce RNA and proteins, or they inhibit specific [genes](#) [5] from doing so. Molecules that activate or inhibit other [genes](#) [5] from producing RNA and proteins are called transcription factors. In *Drosophila* [11], many of those transcription factors are called Cubitus interruptus (Ci), while in vertebrates many are classed in the GLI family of proteins.

The *hh* gene was the focus of much research by developmental biologists in the three decades after its first description. Researchers identified molecules that underpin mechanisms and processes that the hedgehog pathway controls. In the first decades of the twenty-first century, researchers studied the mechanism of how hh proteins function in short-range and long-range signaling between cells. They found that hh proteins distribute in tissues in a steep gradient, with high concentrations near the producing cells and lower amounts farther away from the producing cells. The lipids at either end of the hh ligand have some affinity for hh protein receptors, but their main function is to move the hh ligand through the tissue and establish the gradient.

The [notochord](#) [24], a flexible rod-shaped structure in vertebrate embryos, defines the primary axis of those embryos. The [notochord](#) [24] is located under the [neural tube](#) [25] and it secretes the Shh protein, which forms the gradient. The gradient of Shh protein specifies several distinct neuronal cell fates, designated as V0, V1, V2, and V3 interneurons, and it specifies motor neurons in the [neural tube](#) [25], which is an embryo's precursor to the [central nervous system](#) [26]. The cells of a specialized structure, called the Floor Plate, respond to the highest concentration of Shh protein secreted by the [notochord](#) [24], and they become glial cells, which are cells that support neurons of the nervous system. The Floor Plate glial cells begin to secrete Shh protein themselves. The remaining [neural tube](#) [25] cells develop various neural fates, which are specified by different concentrations of Shh protein signaling. After the Floor Plate forms, the V3 interneurons, motor neurons, V2, and V1 interneurons respond to decreasing concentrations of Shh protein, with V0 interneurons responding to the lowest concentration of Shh protein.

There are similarities between the patterning of the [neural tube](#) [25] in vertebrates and wing

patterning of *Drosophila* [11]. Mutations and improper development of this pathway lead to various embryonic defects and **birth defects** [27], especially those affecting the brain, head, and limbs. Too little hh protein signaling in *Drosophila* [11] can kill embryos or lead to embryos with abnormal wings. In **humans** [12], malfunctions, mutations, and incorrect **regulation** [28] of the hh signaling pathway are commonly associated with **birth defects** [27] and cancers. Cancers such as basal cell carcinoma, which is a skin cancer, or medulloblastoma, which is a brain cancer in children, are potential consequences of mutations to the hh pathway.

If *Shh* activity is lost in mammals, it can lessen the number of cells in the **forebrain** [29] and cause the **forebrain** [29] to fail to develop into two hemispheres. Scientists call the disorder holoprosencephaly. In fetuses, severe cases holoprosencephaly causes brain and facial defects, and the death of the **fetus** [30]. In mild cases, brain development is closer to normal and facial defects are restricted to specific areas, such as cyclopism or having only one eye. Other examples of **birth defects** [27] that result from a mutation in hh signaling are Gorlin syndrome, which increases the risk of tumors, and Greig cephalopolysyndactyly syndrome, which affects head, face, and limb development. People with this disorder can have more digits than normal, webbed digits, a large forehead and head, learning disabilities, and seizures. Because the pathway can control cell proliferation, mutations or too much of the hh signaling in the pathway can lead to cancer.
