Keith Henry Stockman Campbell (1954-2012) [1]

By: Bartlett, Zane

Keith Henry Stockman Campbell studied embryo growth and cell differentiation [7] during the twentieth and twenty-first centuries in the UK. In 1995, Campbell and his scientific team used cells grown and differentiated in a laboratory to clone sheep [8] for the first time. They named these two sheep [9] Megan and Morag. Campbell and his team also cloned a sheep [8] from adult cells in 1996, which they named Dolly. Dolly was the first mammal [9] cloned from specialized adult (somatic) cells with the technique of somatic cell nuclear transfer [10] (SCNT). Campbell helped develop cloning [11] techniques that used a common form of connective tissue cells (fibroblasts). Besides working at the Roslin Institute, in Edinburgh, Scotland, for most of his career, Campbell also taught at the University of Nottingham in Nottingham, England.

Campbell was born 23 May 1954 in Birmingham, England, to Marjorie Regina Smith Campbell and Henry Stockman Campbell. Campbell had one younger sibling, a sister. At age three, Campbell and his family moved to Perth, Scotland, where Campbell began his formal education. His mother noted that he was a curious and adventurous boy who loved the outdoors and she often had to sweep frogs out of the family kitchen after Campbell had brought them home. Campbell returned to Birmingham with his family when he was eight, and he remained in Birmingham until he was twenty-one. Campbell attended school at the King Edward VI Grammar School for boys on a scholarship, but he received no outstanding grades.

At Queen Elizabeth College Campbell studied the mechanisms of life cycles for cells. He graduated in 1978 with a Bachelor of Science in microbiology. After receiving his degree, Campbell worked as a medical technician in southern Yemen until he returned to England a year later. He was in England from 1979 to 1980 as part of a program that aimed to eradicate a fungus that attacks trees, Dutch elm disease, from parts of southern England. Campbell said that he was also unsatisfied with this work.

Campbell began his PhD in 1980 at the Marie Curie Institute in Oxted, England. He joined a group led by Nutan Bishun that studied chromosome structures in cells. Bishun left due to illness shortly after Campbell joined, which left Campbell without a supervisor. Campbell worked alone on his PhD for six months until 1983 when the Marie Curie Institute awarded him a scholarship to study and finish his PhD at the University of Sussex in Sussex, England. There, Campbell studied the cell cycle with the direction of Chris Ford. Campbell learned of a technique to mature egg [12] cells (oocyte [13]) in vitro [14], a technique he later used at the Roslin Institute.

After receiving his PhD, Campbell returned to Scotland. Campbell said he enjoyed mountain biking, hiking, and the outdoors, and he felt that Scotland was where he could enjoy these activities and have a career of his choice. He became a postdoctoral research fellow in the zoology department at Edinburgh University [22] in Edinburgh, Scotland. Campbell joined a group led by Peter Fanties. The group worked to control the cell cycle of Schizosaccharomyces pombe [23], a species of yeast that reproduces by fission. At Edinburgh, Campbell met Murdoch Mitchison, who worked in cellular biology and developed the fission yeast S. pombe as a model system for studying the cell cycle.

In 1989, Campbell left his fellowship in Edinburgh and began another post-doctoral fellowship at the University of Dundee in Dundee, Scotland, where he worked again with Hutchinson on frog [24] embryonic development. In his studies offrog [24] embryos, Campbell studied cell nuclei, and he began to hypothesize about the ability to reprogram an already determined cell. In 1991, Campbell saw a job posting for a post-doctoral position at the Roslin Institute. Later he said that he saw the opportunity as
a better way to provide for his romantic partner, Angela, and for their first daughter Clair, and to pursue cloning [11]. Campbell applied for and received the the job offer. Campbell and Angela later had another daughter named Lauren.

At the Roslin Institute, Campbell met and became friends with Ian Wilmut [25], who led a research group that would eventually clone Dolly. Campbell studied the effects of cloning [11] by transferring the nucleus [19] of one cell to another nuclear transplantation [18]. According to Wilmut, Campbell felt that the key to cloning [11] was to transplant the nucleus [19] to the egg [12] during the second stage of meiosis [26]. Campbell also altered the amounts of Maturation Promoting Factor, or MPF, a protein activity modifier (kinase) that regulates the cell cycle in many animal cells. Campbell and Wilmut first experimented on cattle embryos for this research.

Using the techniques developed with the cattle embryo experiments, Campbell and Wilmut tried cloning [11] sheep [8] because they were cheaper than cattle and because the Roslin Institute already had grown sheep [8] cells in the laboratory. Campbell first tried to clone sheep [8] stem cells [271], but he was unsuccessful because sheep [8] stem cells [27] were difficult to grow in the laboratory.

Two years later, in 1995, Campbell successfully cloned two Welsh Mountain lambs using nuclei from sheep [8] embryo cells grown in the laboratory. Campbell started with a multicelled sheep [8] embryo. He used techniques of mechanical and enzymatic digestion to disassociate the cells apart, and he suspended the individual cells in a liquid. He then placed the cells into cell culture medium [28] and incubated them at thirty-seven degrees centigrade. Those cells were called the primary culture. After several days Campbell removed a portion of the cells from the primary culture and placed them into fresh cell culture media, a process called the first passage. Campbell repeatedly passed cells to new cultures from six to thirteen times, and he used the nuclei from the transferred embryo cells, instead of nuclei from stem cells [27] or primary culture embryo cells, to clone the two lambs.

The researchers transplanted nuclei from the transferred cells into oocytes, each of which had had its original nucleus [19] removed, to form embryos, and then they implanted those embryos into surrogate [29] ewes. When the time was near for the lambs to be born, Campbell, and other members of the team took turns watching the ewes from midnight to five in the morning each day to ensure that the pregnant ewes had no complications. The names of the lambs born in 1996 were Megan and Morag and they were the first cloned sheep [8]. Campbell successfully transplanted nuclei from differentiated embryonic cells because he had discovered how to place these cells into a state called quiescence, which is a state when cell activity is limited. Quiescence more commonly called G0. This resting state is normally unattainable in stem cells [27], but is attainable in differentiated embryonic cells. Wilmut attributed the success of the experiment to Campbell’s hypothesis that if you removed nuclei from differentiated embryonic cells at the G0 stage and transplanted them to oocytes with high MPF, then you could clone differentiated embryonic cells. With the success of Megan and Morag, Campbell insisted that researchers could clone sheep [8] with nuclei from fully differentiated adult cells as well as from differentiated embryonic cells. This claim conflicted with the long-standing theory that once embryonic cells differentiated into specific kinds of adult cells, those adult cells could not return to a totipotent state, or retain the ability to reintegrate the development of a complete organism.

Campbell continued his research with the techniques developed from the Megan and Morag experiment and funding from a new partnership with PPL Therapeutics in Roslin, Scotland. Campbell and his team extracted adult mammary cells from a six-year-old sheep [8] and performed nuclear transplantation [18] from these adult mammary cells into oocytes that had had their original nuclei removed. The team then implanted two hundred seventy-seven embryos, each of which had a nucleus [19] and DNA from an adult mammary cell, into surrogate [29] ewes. One of these attempts resulted in a pregnancy [30] and successful birth of a female sheep [8] in 1997. They named the sheep [8] Dolly, after the singer Dolly Parton. They chose the name because Dolly was cloned from a mammary gland cell and, according to Wilmut, Parton offered an excellent example. Dolly the sheep [8]'s existence helped correct theories about the impossibility of cloning [11] new organisms with differentiated adult cells. Wilmut later said that Campbell was the main contributor to the Dolly project. In a retrospective article, Wilmut claimed that Campbell deserves two thirds of the credit for cloning [11] Dolly.

After Dolly was born, many people discussed the implications for human cloning [11] as well as the authenticity of the experiment. However, genetic tests proved Dolly to be a clone, and accusations of fraud faded. Campbell defended his experiments, but opposed human cloning [11]. At the same time as the Dolly experiment, Campbell cloned two more sheep [8] named Tafty and Tweed from a the nuclei of fetal fibroblast cells. By using fetal fibroblasts, Campbell then helped genetically modify and create a cloned sheep [8] named Polly. Campbell left the Roslin Institute in 1997 during the Polly experiment to become the head of the embryology [83] department for PPL Therapeutics, and he finished the Polly experiment with PPL Therapeutics.

Polly was the first mammal [9] that scientists made to have genes [32] from another species (transgenic) through genetic engineering techniques. Researchers altered Polly’s genes [32] to express Factor IX, which is a human protein that doctors use to treat a type of hemophilia [33], a blood clotting disorder. Campbell’s team incorporated the human Factor IX gene by transfection into embryonic fibroblast cells of sheep [8]. Next they transplanted the fibroblast nuclei into unfertilized sheep [8] oocytes to produce embryos, which they implanted in ewes, one of which yielded Polly. Campbell continued to work with and clone livestock, including sheep [8], pigs, and cattle. In 1999, Campbell helped clone the first gene-targeted mammal [9]. These mammals were sheep [8] named Cupid and Diana. Gene targeting is the process of placing genes [32] on the chromosome exactly
where they will be best expressed and controlled. Campbell's experiments with Cupid and Diana in 1999 led to the first piglets cloned from somatic cells, which were born in the year 2000. Campbell planned to use gene-targeted cloned pigs to transplant tissues from one species of animal to another.

In 1999, Campbell left PPL Therapeutics and became a professor of animal development at the University of Nottingham in Nottingham, England, where he continued his work on cloning [11]. He also tried to make stem cells [27] out of already differentiated cells. According to Wilmut, Campbell did not like bureaucracy and he enjoyed his time as a professor because he was better able to pursue his own research. During his time at Nottingham, Campbell served on scientific advisory boards for various academic organizations and companies. In 2008, Keith Campbell, Ian Wilmut [25], and Shinya Yamanaka [34] in Japan received the Shaw Prize for Medicine and Life Sciences. Campbell died on 5 October 2012 at the age of fifty-eight.
