Process of Eukaryotic Embryonic Development [1]

By: Maayan, Inbar

Keywords: Eukaryotes [2] Ontogeny [3]

All sexually reproducing, multicellular diploid eukaryotes begin life as embryos. Understanding the stages of embryonic development is vital to explaining how eukaryotes form and how they are related on the tree of life. This understanding can also help answer questions related to morphology [6], ethics, medicine, and other pertinent fields of study. In particular, the field of comparative embryology [8] is concerned with documenting the stages of ontogeny [7]. In the nineteenth century, embryologist Karl Ernst von Baer [6] famously noted that embryos of different species generally start out with very similar structure and diverge as they progress through development. This similarity allows for the construction of a series of detailed stages exhibited by a range of different organisms (though in reality embryonic development is a continuous, not staggered, process) describing the progression of events that begin with conception [9].

The formation of the male and female gametes (sex cells) through meiosis [10] makes fertilization [11] possible. The ovum [12], the female gamete, is relatively large (approximately 0.1 mm across in humans [13]) and contains a cytoplasm rich with organelles and substances to be used during development. The spermatozoon [24], the male gametes, are just big enough to carry the male’s DNA in a capsule propelled by a motile tail. Development of viable [15] offspring requires the successful union of ovum [12] and sperm [16], both of which are haploid (contain half the number of somatic chromosomes), to form a diploid cell. In many mammals, the sperm [16] is required to break through a translucent, elastic coating of the ovum [12], known as the zona pellucida [17], before fertilization [11] can take place. Once the spermatozoon has penetrated the ovum [12], a series of physical and chemical changes occur, including the sealing off of the egg [18] to other sperm [16] and the fusion of the parent nuclei. At this point, the egg [18]-sperm [16] complex is referred to as the zygote [19]. The zygote [19] is the first cell of the embryo and contains the genetic information of the new organism. Formation of the zygote [19] is followed by cleavage, which entails a rapid succession of mitotic cell division and results from the migration of cells inward, and thus forms the innermost layer. The particular type of cleavage (radial, bilateral, or spiral) in various organisms helps determine the body plan later in development. The process of cleavage is concerned only with the continuous doubling of the number of blastomeres and not with cellular growth; the result is a ball of cells not larger than the original egg [18] itself. This compact ball of cells, the morula, does not yet exhibit any sign of a future body plan, and, in the case of mammalian embryos, is still contained within the zona pellucida [17]. While in mammals the morula develops into the blastocyst [20] upon continued division of the blastomeres, most other animals’ blastomeres move to form a hollow sphere of cells called the blastula [21]. The blastocyst [20] only differs from the blastula [21] in that it exhibits basic differentiation [22], while the blastula [21] is wholly undifferentiated.

Differentiation, the assignment of a specific fate to pluripotent cells, begins when the blastula [21] progresses through a process known as gastrulation [23]. The gastrula [24] forms through slightly different processes in different types of organisms, the process diverging most from the original in vertebrates, though all but the simplest organisms eventually form a gastrula [24] composed of three germ layers [25]: endoderm [26], mesoderm [27], and ectoderm [29]. Fate maps of the embryo and its layers help illustrate the differentiation [23] of each region. The endoderm [26] results from the migration of cells inward, and thus forms the innermost layer. Its primary fate is the formation of the digestive and respiratory structures, as well as accessory digestive organs such as the pancreas and liver. The outermost germ layer, the ectoderm [28], eventually gives rise to such structures as the nervous system and the epidermis (skin). The mesoderm [27], which lies between the other two germ layers [25], is indicative of progressive evolutionary complexity because it allows for the formation of the body cavity, the coelom, which in turn allows for digestion of food. Mesoderm is not found in animals with only two germ layers [25], such as Porifera [29] (sponges) and Cnidaria [30] (e.g., jellyfish and anemones). The mesoderm [27] gives rise to the vascular and lymphatic systems, as well as to muscle, bone, and connective tissue. It should be noted that the germ layers [25], while fated to give rise to certain structures, do not do so until later in development.

The process of gastrulation [23] has been well documented in such organisms as sea urchins, frogs, and humans [13]. The major steps of a certain developmental path may be observed in each, making the study of these organisms useful for a general understanding of gastrulation [23] and subsequent processes.

Following gastrulation [23], some invertebrates go through a larval stage (for example, the pluteus [31] stage in sea urchins) that lasts until they undergo metamorphosis [32] and transform into the adult form. Vertebrates [33], however, go through neurulation [34] instead of becoming a larva. Neurulation entails the formation of the notochord [35], the creation of the neural tube [36] from which the central nervous system [37] originates, and the formation of the neural crest [38] or neural plate [39], along with neural crest cells [40]. In addition to these components, somites [41] form on either side of the neural tube [39]. Somites are simple, segmented blocks
of cells that will later develop into the individual vertebrae and ribs, and some of the dermis and muscles. The shape of the organism until neurulation is fairly rounded, though during the process the embryo undergoes some elongation and takes a shape similar to a partially coated pea.

Neurulation is closely followed by organogenesis, when the internal organs and organ systems are formed and the entire embryo undergoes significant morphological change. During this time, the embryo becomes longer and flatter, a tail buds at the end of the basic spine, and the head becomes distinct from the rest of the body. In addition, appendages bud and the embryo becomes distinct from the surrounding cells and fluids. The development of the brain, optic organs, and spinal cord follows a noticeable thickening of the neural tube and the formation of small vesicles in the head area. The germ layers differentiate further and become more specifically divided to give rise to the aforementioned systems.

Following organogenesis, the embryo enters a series of stages of growth and further differentiation, which last until the end of the embryonic stage, at which point in mammals it becomes a fetus. It is important to understand that the embryo’s systems are still far from fully developed, and as a fetus, it requires the protection of the womb and its unique conditions.
